1 Introduction

The human nuclear genome contains a large number of highly repeated DNA sequences. The \( Alu \) sequences are primate specific and are the most abundant family of repeated DNA sequences in the human genome. The human \( Alu \) sequence is approximately 300 bp long [2]. The \( L1 \) sequence is a long interspersed nuclear element. \( L1 \) is found in other mammals. Although their functions are not yet clear [4], some of them may affect gene functions or cause human diseases [3].

We have identified repeated DNA sequences from human genomic sequences in the region of \( 3p21.3-p22 \) and \( 9q32 \), both of which are more than 1M bp long. Our statistical analysis shows that the distributions of \( Alu \)s and exons have a weak positive correlation and those of \( L1s \) and exons have a weak negative correlation.

2 Method

Genomic sequence data of the human chromosome \( 3p21.3-p22 \) and \( 9q32 \) as well as cDNA sequences on these regions were obtained by Y. Daigo et al. (unpublished data). The lengths of sequences on the chromosome \( 3p21.3-p22 \) and \( 9q32 \) are 1.2M bp and 1.0M bp respectively. While the region \( 3p21.3-p22 \) contains 14 genes, the region \( 9q32 \) has only 3 genes.

Repetitive sequences were identified by the computer program CENSOR [1] with Repbase (Release 5.0). We divided each sequence into non-overlapping 100k bp segment and counted the exon, \( Alu \) and \( L1 \).

3 Result & Discussion

To characterize the exon, \( Alu \) and \( L1 \) distributions, we compared their densities. The \( Alu \)s and exons were more abundant in the \( 3p21.3-p22 \) region whereas the \( L1s \) were more abundant in the \( 9q32 \) region. To test the significance of these differences, we applied a statistical analysis technique known as two-sample paired \( t \)-test. The significant difference \((p<0.05)\) between the regions was observed in exon and \( Alu \) but not in \( L1 \) (Table 1).

Next, densities of exon, \( Alu \) and \( L1 \) in each 100k bp segment were plotted in Fig. 1. Due to extremely low gene content, no or little tendency was observed in the region \( 9q32 \). In \( 3p21.3-p22 \), positive correlation against exon density was observed for \( Alu (r = 0.42) \) and negative correlation against exon density was observed for \( L1 (r = -0.42) \). When the data in both regions were taken into...
account, the correlation coefficient between exon and Alu densities became 0.62 while that between exon and L1 densities was unchanged \( (r = -0.42) \). However, when the segment size was enlarged up to 170k bp, the latter correlation coefficient also became a large negative value \(-0.7\) (data not shown).

These results suggest that Alu elements but not L1s have a tendency to cluster into regions where the gene density is high. Although existence of direct relationships between exons and repetitive elements is not clear yet, the observed correlations might have an influence on gene function or gene expressions.
